Multiscale adaptively weighted least squares finite element methods for convection-dominated PDEs

Bridget Kraynik, Yifei Sun and Chad R. Westphal

(Communicated by John Baxley)

We consider a weighted least squares finite element approach to solving convection-dominated elliptic partial differential equations, which are difficult to approximate numerically due to the formation of boundary layers. The new approach uses adaptive mesh refinement in conjunction with an iterative process that adaptively adjusts the least squares functional norm. Numerical results show improved convergence of our strategy over a standard nonweighted approach. We also apply our strategy to the steady Navier–Stokes equations.

1. Introduction

In this paper we consider numerically approximating solutions to the convection-diffusion partial differential equation

\[
\begin{aligned}
-\varepsilon \Delta u + b \cdot \nabla u &= f \quad \text{in } \Omega, \\
 u &= g \quad \text{on } \partial \Omega.
\end{aligned}
\]

Here, \( u = u(x, y) \) is the solution, \( \nabla u \) and \( \Delta u \) are the gradient and Laplacian of \( u \), \( \partial \Omega \) is the boundary of domain \( \Omega \), \( f \) is a known data function, \( g \) is a known boundary function, and \( \varepsilon \) and \( b \) are coefficients for diffusion and convection, respectively. For \( \varepsilon \ll |b| \) we say that this represents a convection-dominated diffusion problem. In such cases, solutions tend to develop boundary layers, that is, components of the solution that have steep gradients near the boundary. To illustrate this, consider the following ordinary differential equation analogy:

\[
\begin{aligned}
-\varepsilon u'' + bu' &= 0 \quad \text{in } (0, 1), \\
u(0) &= 1, \\
u(1) &= 0.
\end{aligned}
\]

where $bu'$ is the convection term and $-\varepsilon u''$ the diffusion term. We call the ODE convection-dominated when $\varepsilon \ll |b|$, and to illustrate this we set $b = 1$ and consider the following solution plots for different values of $\varepsilon$ in Figure 1.

We can see that as $\varepsilon \to 0$, a boundary layer forms near $x = 1$. This behavior is difficult to approximate computationally and is also present in the solution of system (1) for regions of $\Omega$ near boundary points with $n \cdot b > 0$, where $n$ is an outward unit normal to $\partial \Omega$. See [Brenner and Scott 1994; Braess 2001] for background on finite element methods for such problems.

The method we develop here is a generalization of a least squares finite element discretization for scalar elliptic equations. In general, a least squares approach to (1) tends to be an effective way to approximate solutions; however, convergence is degraded in the presence of dominant convection. We consider a least squares functional minimized with respect to a weighted $L^2$-norm, where the weights are chosen adaptively in the context of an adaptive mesh refinement routine. This idea is inspired by work of Westphal et al. [Lee et al. 2006; 2008; Cai and Westphal 2008], where a weighted functional is used to improve solutions to problems with singularities.

The organization of this paper is as follows: in Section 2 we introduce a reformulated version of (1) and the adaptively weighted procedure; in Section 3 we provide several numerical tests to demonstrate the effectiveness of the method compared to a more standard approach; and in Section 4 we show the robustness of the idea by applying it analogously to a moderately high Reynolds number Navier–Stokes system for steady fluid flow.

### 2. Methodology

The $L^2(\Omega)$ norm of a function $f$ is defined to be

$$\|f\| = \|f\|_{L^2(\Omega)} = \left( \int_{\Omega} |f|^2 \right)^{1/2},$$

and $L^2(\Omega)$ is the space of functions in $\Omega$ that have finite $L^2(\Omega)$ norms. Likewise, we define $H^1(\Omega)$ as the subspace of $L^2(\Omega)$ where all first partial derivatives of functions are also in $L^2(\Omega)$. 
With the substitution $\sigma = -\varepsilon \nabla u$, we rewrite (1) as the first-order equations

$$\begin{align*}
\nabla \cdot \sigma + b \cdot \nabla u &= 0 \quad \text{in } \Omega, \\
\sigma + \varepsilon \nabla u &= 0 \quad \text{in } \Omega, \\
\nabla \times \sigma &= 0 \quad \text{in } \Omega, \\
u &= g \quad \text{on } \partial \Omega, \\
\hat{\tau} \cdot \sigma &= -\varepsilon \hat{\tau} \cdot \nabla g \quad \text{on } \partial \Omega.
\end{align*}$$

(3)

The third equation holds because $\nabla \times \sigma = \nabla \times (-\varepsilon \nabla u) = -\varepsilon (\nabla \times \nabla u) = 0$. In the fifth equation, $\hat{\tau}$ is a unit tangent vector to $\partial \Omega$ and this new boundary condition is simply a statement about the directional derivative of $g$ along $\partial \Omega$.

We first consider what we refer to as the standard least squares approach. Since we seek a finite element solution, we partition $\Omega$ into an initial triangulation denoted as $\Omega^h$. Here, $h$ denotes the size, or width of the triangles and $(u^h, \sigma^h)$ represents an approximate solution to $(u, \sigma)$, the exact solution of system (3). Define

$$V = \{v \in H^1(\Omega) : v = g \text{ on } \partial \Omega\},$$

$$\Sigma = \{s \in H^1(\Omega)^2 : \tau \cdot s = -\varepsilon \tau \cdot \nabla g \text{ on } \partial \Omega\}$$

as sets of admissible solutions, and let $V^h \subseteq V$ and $\Sigma^h \subseteq \Sigma$ be finite dimensional subsets in which we seek approximate solutions.

A standard LS approach seeks a pair of solutions $(u^h, \sigma^h) \in V^h \times \Sigma^h$ which minimizes the functional

$$G(u^h, \sigma^h; f) = \|\nabla \cdot \sigma^h + b \cdot \nabla u^h - f\|^2 + \|\sigma^h + \varepsilon \nabla u^h\|^2 + \|\nabla \times \sigma^h\|^2.$$  

(4)

For elliptic problems that are diffusion dominated, minimizing (4) using standard finite element spaces results in good convergence. However, for convection-dominated problems, minimizing (4) results in slow convergence until $h$ is very small (typically $h \approx \mathcal{O}(\varepsilon)$). Other finite element approaches tend to be unstable in convection-dominated regimes and solutions may exhibit oscillatory behavior; see, e.g., [Bochev and Gunzburger 2009; Strang and Fix 1973].

One undesirable aspect of the standard least squares approach is that there is not only significant error near boundary layers, but that the error may remain large even in regions of the domain where the solution is smooth. To reduce this “pollution effect”, we introduce weight functions into the functional (4) to redefine the metric of the approximation space. By doing this, we are able to force the least squares functional to choose a better solution globally (i.e., in the regions of the domain where the solution is smooth) and segregate errors to a small region near boundary layers. Thus, we want to choose the weight function, $w$, to be large (a value at or near 1) where the error is small, and small (a value near 0) where the error is large.
In this paper we use what we call a sigma-based weighting strategy that uses the approximate solution for $\sigma$ to construct the weight function. An alternative, one we refer to as functional based weighting, uses locally evaluated functional values to generate weights. Though both strategies have merits, we focus here on sigma-based weights. Consider an approximate solution $\sigma^h$ evaluated on a single finite element triangle, $T$:

$$\|\sigma^h\|_T = \left( \int_T |\sigma^h|^2 \right)^{1/2},$$

which we may use as a local indicator of where the solution is likely to have steep gradients (recall the definition of $\sigma$). We thus choose a weight function, $w$, on each $T$ by the procedure illustrated in Figure 2.

We choose $w_{\min} = e^{-h/\varepsilon}$. For coarse meshes, where weighting is most needed, $w_{\min}$ is very near zero. For increasingly fine meshes, where the weight procedure is needed less, we have $\lim_{h \to 0} w_{\min} \to 1$. Thus our algorithm remains robust for a wide range of convection-diffusion regimes.

With such an appropriate weight function chosen we find an improved approximate solution by choosing $u^h$ and $\sigma^h$ that minimize the weighted least squares functional

$$G(u^h, \sigma^h; f) = \|w(\nabla \cdot \sigma^h + b \cdot \nabla u^h - f)\|^2 + \|w(\sigma^h + \varepsilon \nabla u^h)\|^2 + \|w(\nabla \times \sigma^h)\|^2,$$

(5)

where we note that setting $w = 1$ corresponds to the original least squares functional (4). Since this approach obviously requires an initial approximate solution to choose $w$, it makes sense to conduct this in a nested iteration approach where the initial approximation is found cheaply on a coarse mesh and the improved approximation is found on refined mesh. In other words, our approach is to incorporate

![Figure 2](image-url)  

**Figure 2.** The relationship between $\|\sigma^h\|_T$ and the weight function.
refining the weight function in (5) into an adaptive mesh refinement routine for finding increasingly accurate approximations on a sequence of refined meshes.

We describe the solution process in the following algorithm:

- **Start**: Consider minimizing (5) on an initial coarse triangulation $\Omega^H$, where $H$ is the mesh size. Initially set $w = 1$.

- **Coarse solve**: Minimize (5) to find $(u^H, \sigma^H) \in V^H \times \Sigma^H$.

- **Construct weights**: Using the rule illustrated in Figure 2, choose $w$ to be a piecewise linear function on each element in $\Omega^H$.

- **Refine mesh**: The locally evaluated least squares functional is used to determine triangles in $\Omega^H$ with the highest concentration of error, which are refined by splitting each into four smaller triangles. Let $h = H/2$ represent the mesh size of the refined mesh, $\Omega^h$.

- **Fine solve**: Minimize (5) to find $(u^h, \sigma^h) \in V^h \times \Sigma^h$. Set $H \leftarrow h$ as the coarse scale for the problem and repeat the procedure.

Figure 3 illustrates the multilevel iterative algorithm.

Figure 3. Iterative process for computing approximate solutions: coarse mesh, coarse solution, weight function, refined mesh, fine solution.
3. Testing and results

We test several problems with various levels of difficulty. We compare our approximate solution \((u_h, \sigma_h)\) to a control solution to get the associated error. This control solution is obtained by computing the solution on a superfine scale mesh using the standard LS approach over several iterations. We assume it to be sufficiently accurate for our purpose of comparison. We compute the \(L^2\) norm of this error as a measure of accuracy of the approximated solution. In all cases we use conforming piecewise quadratic finite elements for each unknown. In the computational tests in this section, we choose \(\Omega = (0, 1)^2\) and zero Dirichlet boundary conditions on the north, east and west boundaries, and define a nonzero \(g(x)\) on the south boundary.

The following four examples compare the efficiency of the standard LS approach and our sigma-based weighting strategy. Both axes in all graphs are on a \(\log_{10}\) scale. The points that are higher have larger errors than the lower ones.

**Example 1.** We solve the system (1) with a constant \(b = (-\frac{1}{\sqrt{10}}, \frac{3}{\sqrt{10}})\), a smooth \(g = 16x^2(1-x)^2\), and a relatively large \(\varepsilon = 0.005\). The results are shown in Figure 4; it can be seen that our sigma-based weighting method yields a more accurate solution (by a factor of 3 approximately) than the standard LS approach.

**Example 2.** Next we take a nonconstant convection coefficient, \(b = \left(\frac{-y}{\sqrt{x^2 + y^2}}, \frac{x}{\sqrt{x^2 + y^2}}\right)\), with \(g\) and \(\varepsilon\) as in Example 1. The results, shown in Figure 5, show that our approach still outperforms the standard one, though by a lesser factor than before.

![Figure 4. Log-log plot of \(L^2\) norm of error (with respect to control solution) as a function of the number of triangles, for \(b = (-\frac{1}{\sqrt{10}}, \frac{3}{\sqrt{10}}), g = 16x^2(1-x)^2, \varepsilon = 0.005\) (Example 1).](image-url)
Figure 5. Like Figure 4, with $b = \left(-\frac{y}{\sqrt{x^2 + y^2}}, \frac{x}{\sqrt{x^2 + y^2}}\right)$, $g = 16x^2(1-x)^2$, $\varepsilon = 0.005$ (Example 2).

Figure 6. Like Figure 4, with $g$ discontinuous (Example 3).

Example 3. We return to $b$ and $\varepsilon$ as in Example 1, and choose a discontinuous boundary function,  
\[
g = \begin{cases} 
1 & \text{if } x \in (0.2, 0.8), \\
0 & \text{else.}
\end{cases}
\]

Here the two curves (Figure 6) come even closer than in the previous example, but the solution with sigma-based weights is still the more accurate one. With discontinuous data on the boundary, the solution here is much more difficult to approximate numerically, so the overall error is larger than the previous examples.

Example 4. For our final example in this section, we decrease $\varepsilon$ by an order of magnitude, that is, $\varepsilon = 0.0005$, while $b = \left(-\frac{1}{\sqrt{10}}, \frac{3}{\sqrt{10}}\right)$ and $g = 16x^2(1-x)^2$ stay
the same as in Example 1. Here again, our method shows an improvement over the standard approach (Figure 7).

4. Results for Navier–Stokes equations

The preceding examples suggest that the sigma-based weighting method is generally more efficient than the standard LS approach. As a further case study, we consider a more complicated system of equations that retains the same set of challenges as the convection-dominated diffusion problem.

In this section we directly apply the adaptively weighted norm minimization strategy to a more difficult system of equations. We consider the stationary incompressible Navier–Stokes equations in the form

\[
\begin{aligned}
\frac{-1}{\text{Re}} \Delta u + u \cdot \nabla u + \nabla p &= f \quad \text{in } \Omega, \\
\nabla \cdot u &= 0 \quad \text{in } \Omega, \\
\nabla \cdot u &= g \quad \text{on } \partial \Omega,
\end{aligned}
\]

where \( u \) denotes the velocity of fluid flow in the \( x \) and \( y \) direction, \( p \) the pressure of fluid flow, \( f \) a given body force, and \( \text{Re} \) denotes the Reynolds number, a measure of the potential turbulence of the fluid. With the two substitutions

\[ \varepsilon = \frac{1}{\text{Re}} \quad \text{and} \quad U = -\varepsilon \nabla u, \]

the first equation in (6) becomes

\[
\nabla \cdot U + u \cdot \nabla u + \nabla p = f.
\]
Utilizing a Newton linearization, we have the following approximation

\[ \mathbf{u} \cdot \nabla \mathbf{u} \approx \mathbf{u}_{\text{old}} \cdot \nabla \mathbf{u} + \mathbf{u} \cdot \nabla \mathbf{u}_{\text{old}} - \mathbf{u}_{\text{old}} \cdot \nabla \mathbf{u}_{\text{old}}, \]

where \( \mathbf{u}_{\text{old}} \approx \mathbf{u} \) is a known approximation to \( \mathbf{u} \). This current solution, \( \mathbf{u}_{\text{old}} \), is initially set to be \((0, 0)\). During the iteration process, each time we obtain a new approximate solution to \( \mathbf{u} \), we assign its value to \( \mathbf{u}_{\text{old}} \). Therefore, the older \( \mathbf{u}_{\text{old}} \) in (6) will be replaced by the new one to better approximate the left-hand side of (6). After the substitution, (6) is reformulated as

\[
\begin{align*}
\nabla \cdot \mathbf{U} + \mathbf{u}_{\text{old}} \cdot \nabla \mathbf{u} + \mathbf{u} \cdot \nabla \mathbf{u}_{\text{old}} + \nabla p &= f + \mathbf{u}_{\text{old}} \cdot \nabla \mathbf{u}_{\text{old}} \quad \text{in } \Omega, \\
\mathbf{U} + \varepsilon \nabla \mathbf{u} &= 0 \quad \text{in } \Omega, \\
\nabla \times \mathbf{U} &= 0 \quad \text{in } \Omega, \\
\nabla \cdot \mathbf{u} &= 0 \quad \text{in } \Omega, \\
\mathbf{u} &= \mathbf{g} \quad \text{on } \partial \Omega.
\end{align*}
\]

Notice the similarity between this system and (3), which gives us confidence that the weighted norm procedure can improve a least squares solution method for this system. For large Re, turbulent flow characteristics, including boundary layers, may develop, which is similar to the behavior of convection-dominated PDEs. Therefore, we define our weighted, linearized LS functional to be

\[
G(\mathbf{u}, \mathbf{U}, p; f) = ||w(\nabla \cdot \mathbf{U} + \mathbf{u}_{\text{old}} \cdot \nabla \mathbf{u} + \mathbf{u} \cdot \nabla \mathbf{u}_{\text{old}} + \nabla p) - (f + \mathbf{u}_{\text{old}} \cdot \nabla \mathbf{u}_{\text{old}})||^2 + ||w(\mathbf{U} + \varepsilon \nabla \mathbf{u})||^2 + ||w(\nabla \times \mathbf{U})||^2 + ||w(\nabla \cdot \mathbf{u})||^2,
\]

where \( w \) denotes our weight function. On each mesh we carry out several steps of Newton linearization, and then adaptively refine our mesh. Weight functions are now constructed based on \( \mathbf{U} \) (which is analogous to \( \sigma \) in the convection-dominated diffusion system).

To test our weighting strategy, we choose our domain \( \Omega \) to be \((0, 1)^2 \setminus (0, 0.5)^2\). We set \( \varepsilon = 1/200 \) and \( \mathbf{u} = ((1 - e^{-(y-0.5)/\varepsilon})(1 - e^{-(1-y)/\varepsilon}), 0) \) on the upper west boundary and \( \mathbf{u} = (0, -(1 - e^{-(x-0.5)/\varepsilon})(1 - e^{-(1-x)/\varepsilon})) \) on the south boundary. We again set \( f \) to be 0 for simplicity. Figure 8 shows the control solution for our test problem.

We set the number of Newton linearization steps on each mesh to 3. Figure 9 compares the accuracy of both approaches to solving Navier–Stokes equations. The \( x \)- and \( y \)-axis are on a log\(_{10}\) scale.

The result shows again that our sigma-based weighting method is more efficient at solving the Navier–Stokes equations than having no weight functions.
**Figure 8.** The control solution for $u_1$ (left) and $u_2$ (right), obtained on a fine mesh and presumed very accurate.

**Figure 9.** Comparison of weighted and nonweighted approaches for the Navier–Stokes example (log-log plot).

### 5. Conclusion

We find that defining and adaptively modifying weight functions in a least squares functional can improve the efficiency of the method for convection-dominated problems. Our approach uses approximate solutions on coarse meshes to adapt the metric of the approximation space so that the error is reduced with respect to a better scaled norm than a standard approach. The procedure is easily adapted to more difficult convection-dominated problems, such as the steady Navier–Stokes equations.
