TV-MIN AND GREEDY PURSUIT FOR CONSTRAINED JOINT SPARSITY AND APPLICATION TO INVERSE SCATTERING
This paper proposes a general framework for compressed sensing of constrained joint sparsity (CJS) which includes total variation minimization (TV-min) as an example. The gradient- and 2-norm error bounds, independent of the ambient dimension, are derived for the CJS version of basis pursuit and orthogonal matching pursuit. As an application the results extend Candès, Romberg, and Tao’s proof of exact recovery of piecewise constant objects with noiseless incomplete Fourier data to the case of noisy data.

1. Introduction

One of the most significant developments of the last decade in imaging and signal processing is compressive sensing (CS) which promises reconstruction with fewer data than the ambient dimension. CS capability [Candès and Tao 2005; Donoho 2006] hinges on favorable sensing matrices and enforcing a key piece of prior knowledge, that is, sparse objects.

Consider the linear inverse problem

$$Y = \Phi X + E$$

where $X \in \mathbb{C}^m$ is the sparse object vector to be recovered, $Y \in \mathbb{C}^n$ is the measurement data vector, and $E \in \mathbb{C}^n$ represents the (model or external) errors. The great insight of CS is that the sparseness of $X$, as measured by the sparsity $\|X\|_0 \equiv \#$ of nonzero elements in $X$, can be effectively enforced by $\ell_1$-minimization ($\ell_1$-min) [Chen et al. 2001; Donoho and Huo 2001]:

$$\min \|Z\|_1 \quad \text{subject to (s.t.)} \quad \|\Phi Z - Y\|_2 \leq \|E\|_2,$$

with favorable sensing matrices $\Phi$.

The $\ell_1$-min idea dates back to geophysics research in the 1970s [Claerbout and Muir 1973; Taylor et al. 1979]. The $\ell_1$-minimizer is often a much better approximation of the sparse object than the traditional minimum energy solution.
via $\ell_2$-minimization because the $1$-norm is closer to $\| \cdot \|_0$ than the $2$-norm. Moreover, the $\ell_1$-min principle is a convex optimization problem and can be efficiently computed. The $\ell_1$-min principle is effective in recovering the sparse object with a number of data points $n$ much smaller than $m$ if the sensing matrix $\Phi$ satisfies some favorable conditions such as the restricted isometry property (RIP) [Candès and Tao 2005]: $\Phi$ is said to satisfy the RIP of order $k$ if

$$\left(1 - \delta_k\right)\|Z\|_2^2 \leq \|\Phi Z\|_2^2 \leq \left(1 + \delta_k\right)\|Z\|_2^2$$

for any $k$-sparse vector $Z$ where the minimum of such a constant $\delta_k$ is the restricted isometry constant (RIC) of order $k$.

The drawback of the RIP is that only a few special types of matrices are known to satisfy it, including independently and identically distributed (i.i.d.) random matrices and random partial Fourier matrices formed by random row selections of the discrete Fourier transform.

A more practical alternative CS criterion is furnished by the incoherence property as measured by one minus the mutual coherence [Donoho and Elad 2003; Tropp 2004]:

$$\mu(\Phi) = \max_{i \neq j} \frac{\left|\sum_k \Phi_{ik}^* \Phi_{kj}\right|}{\sqrt{\sum_k |\Phi_{ki}|^2} \sqrt{\sum_k |\Phi_{kj}|^2}}.$$  

A parallel development in image denoising pioneered by Osher and coworkers [Rudin et al. 1992; Rudin and Osher 1994] seeks to enforce edge detection by total variation minimization (TV-min):

$$\min \int |\nabla g| \quad \text{s.t.} \quad \int |g - f|^2 \leq \varepsilon^2,$$

where $f$ is the noisy image and $\varepsilon$ is the noise level. The idea is that for the class of piecewise constant functions, the gradient is sparse and can be effectively enforced by TV-minimization.

For digital images, the TV-min approach to deblurring can be formulated as follows. Let $f \in \mathbb{C}^{p \times q}$ be a noisy complex-valued data set of $p \times q$ pixels. Let $T$ be the transformation from the true object to the ideal sensors, modeling the imaging process. Replacing the total variation in (4) by the discrete total variation

$$\|g\|_{TV} \equiv \sum_{i,j} \sqrt{|\Delta_1 g(i, j)|^2 + |\Delta_2 g(i, j)|^2},$$

$$\Delta g = (\Delta_1 g, \Delta_2 g)(i, j) \equiv (g(i + 1, j) - g(i, j), g(i, j + 1) - g(i, j)),$$

we obtain

$$\min \|g\|_{TV} \quad \text{s.t.} \quad \|Tg - f\|_2 \leq \varepsilon$$

(see [Chambolle and Lions 1997; Chan and Shen 2005]).
In a breakthrough paper, Candès et al. [2006] show the equivalence of (5) to (1) for a random partial Fourier matrix with noiseless data ($\epsilon = 0$) and obtain a performance guarantee of exact reconstruction of piecewise constant objects from (5).

A main application of this present work is to extend the result of Candès et al. to inverse scattering with noisy data. In this context it is natural to work with the continuum setting in which the object is a vector in an infinite-dimensional function space, for example, $L^2(\mathbb{R}^d)$. To fit into CS’s discrete framework, we discretize the object function by pixelating the ambient space with a regular grid of equal spacing $\ell$.

The grid spacing $\ell$ can be thought of as the resolution length, the fundamental parameter of the discrete model from which all other parameters are derived. For example, the total number of resolution cells is proportional to $\ell^{-d}$, that is, $m = O(\ell^{-d})$. As we will assume that the original object is well approximated by the discrete model in the limit $\ell \to 0$, the sparsity $s$ of the edges of a piecewise constant object is proportional to $\ell^{1-d}$, that is, the object is nonfractal. It is important to keep in mind the continuum origin of the discrete model in order to avoid confusion about the small $\ell$ limit throughout the paper.

First we introduce the notation for multivectors $Y \in \mathbb{C}^{n \times d}$:

$$\|Y\|_{b,a} = \left(\sum_{j=1}^{n} \|\text{row}_j(Y)\|^b_a\right)^{1/b}, \quad a, b \geq 1,$$

where $\text{row}_j(Y)$ is the $j$-th row of $Y$. The 2, 2-norm is exactly the Frobenius norm. To avoid confusion with the subordinate matrix norm [Golub and Van Loan 1996], it is more convenient to view $Y$ as multivectors rather than a matrix.

We aim at the following error bounds. Let $V$ be the discretized object and $\hat{V}$ an estimate of $V$. We will propose a compressive sampling scheme that leads to the error bound for the TV-minimizer $\hat{V}$:

$$\|\Delta V - \Delta \hat{V}\|_{2,2} = O(\epsilon), \quad \ell \to 0,$$

implying via the discrete Poincaré inequality that

$$\|V - \hat{V}\|_2 = O(\epsilon / \ell).$$

independent of the ambient dimension $d$.

If $\hat{V}$ is the reconstruction by using a version of the greedy algorithm, orthogonal matching pursuit (OMP) [Pati et al. 1993; Davis et al. 1997], for multivectors then in addition to (7) we also have

$$\|V - \hat{V}\|_2 = O(\epsilon / \sqrt{\ell})$$

independent of the ambient dimension $d$ (see Section 3). We do not know if the bound (9) applies to the TV-minimizer.
A key advantage of the greedy algorithm used to prove (9) is the exact recovery of the gradient support (that is, the edge location) under proper conditions (Theorem 2 in Section 3). On the one hand, TV-min requires fewer data points for recovery: $\mathcal{O}(s)$ for TV-min under the RIP versus $\mathcal{O}(s^2)$ for the greedy algorithm under incoherence where the sparsity $s = \mathcal{O}(\ell^{1-d})$ is as already mentioned. On the other hand, the greedy algorithm is computationally more efficient and incoherent measurements are much easier to design and verify than the RIP.

At heart our theory is based on reformulation of TV-min as CS of joint sparsity with linear constraints (such as the curl-free constraint in the case of TV-min): basis pursuit denoising (BPDN) for constrained joint sparsity (CJS) is formulated as

$$\min \|Z\|_{1,2}, \quad \text{s.t. } \|Y - \varphi(Z)\|_{2,2} \leq \varepsilon, \quad \mathcal{L}Z = 0,$$

where

$$\varphi(Z) = [\Phi_1 Z_1, \ldots, \Phi_d Z_d], \quad Z_j = \text{the } j\text{-th column of } Z,$$

and $\mathcal{L}$ represents a linear constraint. Without loss of generality, we assume the matrices $\{\Phi_j\} \subset \mathbb{C}^{n \times m}$ all have unit 2-norm columns.

In connection to TV-min, $Z_j$ is the $j$-th directional gradient of the discrete object $V$. And from the definition of discrete gradients, it is clear that every measurement of $Z_j$ can be deduced from two measurements of the object $V$, slightly shifted in the $j$-th direction with respect to each other. As shown below, for inverse scattering we have $\Phi_j = \Phi$ for all $j$, and $\mathcal{L}$ is the curl-free constraint which takes the form

$$\Delta_1 Z_2 = \Delta_2 Z_1$$

for $d = 2$ (see (53)). Our main results, Theorems 1 and 2, constitute performance guarantees for CJS based, respectively, on the RIP and incoherence of the measurement matrices $\Phi_j$.

1.1. Comparison of existing theories. The gradient-based method of [Patel et al. 2012] modifies the original Fourier measurements to obtain Fourier measurements of the corresponding vertical and horizontal edge images which then are separately reconstructed by the standard CS algorithms. This approach attempts to take advantage of typically lower separate sparsity and is different from TV-min. Nevertheless, a similar 2-norm error bound [Patel et al. 2012, Proposition V.2] to (8) is obtained.

Needell and Ward [2012] obtain interesting results for anisotropic total variation (ATV) minimization in terms of the objective function

$$\|g\|_{\text{ATV}} \equiv \sum_{i,j} |\Delta_1 g(i, j)| + |\Delta_2 g(i, j)|.$$

While for real-valued objects in two dimensions, the isotropic TV seminorm is
equivalent to the anisotropic version, the two seminorms are, however, not the same in dimension greater than 3 and/or for complex-valued objects. A rather remarkable result of Needell and Ward is the bound $\| V - \hat{V} \|_2 = \Theta(\varepsilon)$, modulo a logarithmic factor, for $d = 2$. This is achieved by proving a strong Sobolev inequality for two dimensions under the additional assumption of the RIP with respect to the bivariate Haar transform. Unfortunately, this latter assumption prevents the results in [Needell and Ward 2012] from being directly applicable to structured measurement matrices such as Fourier-like matrices which typically have high mutual coherence with any compactly supported wavelet basis when adjacent subbands are present. Their approach also does not guarantee exact recovery of the gradient support.

It is worthwhile to further consider these existing approaches from the perspective of the CJS framework for arbitrary $d$. The approach of [Patel et al. 2012] can be reformulated as solving $d$ standard BPDNs

$$\min \| Z_\tau \|_1, \quad \text{s.t.} \quad \| Y_\tau - \Phi Z_\tau \|_2 \leq \varepsilon, \quad \tau = 1, \ldots, d,$$

separately without the curl-free constraint $\mathcal{L}$ where $Z_\tau$ and $Y_\tau$ are, respectively, the $\tau$-th columns of $Z$ and $Y$. To recover the original image from the directional gradients, an additional step of consistent integration becomes an important part of the approach in [Patel et al. 2012].

From the CJS perspective, the ATV-min considered in [Needell and Ward 2012] can be reformulated as follows. Let $\tilde{Z} \in \mathbb{C}^{dm}$ be the image gradient vector by stacking the $d$ directional gradients and let $\tilde{Y} \in \mathbb{C}^{dn}$ be the similarly concatenated data vector. Likewise let $\tilde{\Phi} = \text{diag}(\Phi_1, \ldots, \Phi_d) \in \mathbb{C}^{dn \times dm}$ be the block-diagonal matrix with blocks $\Phi_j \in \mathbb{C}^{n \times m}$. Then ATV-min is equivalent to BPDN for a single constrained and concatenated vector:

$$\min \| \tilde{Z} \|_1, \quad \text{s.t.} \quad \| \tilde{Y} - \tilde{\Phi} \tilde{Z} \|_2 \leq \varepsilon, \quad \tilde{\mathcal{L}} \tilde{Z} = 0, \quad (11)$$

where $\tilde{\mathcal{L}}$ is the same constraint $\mathcal{L}$ reformulated for concatenated vectors. Repeating verbatim the proofs of Theorems 1 and 2 we obtain the same error bounds as (7)–(9) for ATV-min as formulated in (11) under the same conditions for $\Phi_j$ separately.

In [Needell and Ward 2012], ATV-min is formulated in terms of the image, instead of the image gradient, to get rid of the curl-free constraint. To proceed the differently concatenated matrix $[\Phi_1, \ldots, \Phi_d]$ is then assumed to satisfy the RIP of higher order demanding $2dn$ measurement data points. For $d = 2$, Needell and Ward assume the RIP of order $5s$ with $\delta_{5s} < \frac{1}{3}$ for $[\Phi_1, \Phi_2]$, which is much more stringent than the RIP of order $2s$ with $\delta_{2s} < \sqrt{2} - 1$ for $\Phi_1$ and $\Phi_2$ separately in (11). In particular, $\Phi_1 = \Phi_2$ is allowed for (11) but not for Needell and Ward. To get the aforementioned favorable $\Theta(\varepsilon)$ 2-norm error bound for $d = 2$, an additional measurement matrix satisfying the RIP with respect to the bivariate Haar basis is needed, which, as mentioned above, excludes partial Fourier measurements.
1.2. Organization. The rest of the paper is organized as follows. In Section 2, we present a performance guarantee for BPDN for CJS and obtain error bounds. In Section 3, we analyze the greedy approach to sparse recovery of CJS and derive error bounds, including an improved 2-norm error bound. In Section 4, we review the scattering problem starting from the continuum setting and introduce the discrete model. In Section 5, we discuss various sampling schemes including the forward and backward sampling schemes for inverse scattering for point objects. In Section 6 we formulate TV-min for piecewise constant objects as BPDN for CJS. We present numerical examples and conclude in Section 7. We present the proofs in the Appendices.

2. BPDN for CJS

Consider the linear inversion problem
\[ Y = \varphi(X) + E, \quad \mathcal{L}X = 0, \tag{12} \]
where
\[ \varphi(X) = [\Phi_1 X_1, \Phi_2 X_2, \ldots, \Phi_d X_d], \quad \Phi_j \in \mathbb{C}^{n \times m}, \]
and the corresponding BPDN
\[
\min \|Z\|_{1,2}, \quad \text{s.t.} \quad \|Y - \varphi(Z)\|_{2,2} \leq \|E\|_{2,2}, \quad \mathcal{L}Z = 0. \tag{13}
\]
For TV-min in \( d \) dimensions, \( \Phi_j = \Phi \) for all \( j \), the vector \( X \) represents the discrete gradient of the unknown object \( V \), and \( \mathcal{L} \) is the curl-free constraint. Without loss of generality, we assume the matrices \( \{\Phi_j\} \) all have unit 2-norm columns.

We say that \( X \) is \( s \)-row sparse if the number of nonzero rows in \( X \) is at most \( s \). With a slight abuse of terminology we call \( X \) the object (of CJS).

In the following theorems, we let the object \( X \) be general, not necessarily \( s \)-row sparse. Let \( X^{(s)} \) consist of the \( s \) largest rows in the 2-norm of \( X \). Then \( X^{(s)} \) is the best \( s \)-row sparse approximation of \( X \).

**Theorem 1.** Suppose that the linear map \( \varphi \) satisfies the RIP of order \( 2s \)
\[
(1 - \delta_{2s}) \|Z\|_{2,2}^2 \leq \|\varphi(Z)\|_{2,2}^2 \leq (1 + \delta_{2s}) \|Z\|_{2,2}^2 \tag{14}
\]
for any \( 2s \)-row sparse \( Z \) with \( \delta_{2s} < \sqrt{2} - 1 \). Let \( \hat{X} \) be the minimizer of (13). Then
\[
\|\hat{X} - X\|_{2,2} \leq C_1 s^{-1/2} \|X - X^{(s)}\|_{1,2} + C_2 \varepsilon \tag{15}
\]
for absolute constants \( C_1 \) and \( C_2 \) depending only on \( \delta_{2s} \).

**Remark 1.** Note that the RIP for joint sparsity (14) follows straightforwardly from the assumption of the separate RIP:
\[
(1 - \delta_{2s}) \|Z\|_{2}^2 \leq \|\Phi_j Z\|_{2}^2 \leq (1 + \delta_{2s}) \|Z\|_{2}^2 \quad \text{for all} \quad j,
\]
with a common RIC.

**Remark 2.** For the standard Lasso with a particular choice of regularization parameter, [Candès and Plan 2009, Theorem 1.3] guarantees exact support recovery under a favorable sparsity constraint. In our setting and notation, their TV-min principle suggests

\[
\min_{\mathcal{Z}} \lambda \sigma \| \mathcal{Z} \|_{1,2} + \frac{1}{2} \| Y - \varphi(\mathcal{Z}) \|_{2,2}^2, \quad \lambda = 2\sqrt{2 \log m},
\]

where \( \sigma^2 = \varepsilon^2/(2n) \) is the variance of the assumed Gaussian noise in each entry of \( Y \). Unfortunately, even if the result of Candès and Plan can be extended to (16), it is inadequate for our purpose because they assume independently selected support and signs, which is clearly not satisfied by the gradient of a piecewise constant object.

The proof of Theorem 1 is given in Appendix A.

The error bound (15) implies (7) for \( s \)-row sparse \( X \). For the 2-norm bound (8), we apply the discrete Poincaré inequality [Cheung 1998]

\[
\| f \|_2^2 \leq \frac{m^{2/d}}{4d^2} \| \Delta f \|_2^2
\]

to get

\[
\| V - \hat{V} \|_2 \leq \frac{m^{1/d}}{2d^{1/2}} C_2 \varepsilon = \mathcal{O}\left( \frac{\varepsilon}{\ell} \right),
\]

since \( \ell \sim m^{-1/d} \).

### 3. Greedy pursuit for CJS

One idea to improve the error bound is through exact recovery of the support. This can be achieved by greedy algorithms. As before, we consider the general linear inversion with CJS (12) with \( \| E \|_{2,2} = \varepsilon \).

**Algorithm 1** on the next page is an extension of the joint-sparsity greedy algorithms of [Cotter et al. 2005; Chen and Huo 2006; Tropp et al. 2006] to a setting with multiple sensing matrices.

Note that the linear constraint is not enforced in **Algorithm 1**.

A natural indicator of the performance of OMP is the mutual coherence (3) [Tropp 2004; Donoho et al. 2006]. Let

\[
\mu_{\max} = \max_j \mu(\Phi_j).
\]

Then, analogous to [Donoho et al. 2006, Theorem 5.1], we have the following performance guarantee.
Theorem 2. Suppose the sparsity $s$ satisfies

$$s < \frac{1}{2} \left( 1 + \frac{1}{\mu_{\max}} \right) - \frac{\sqrt{d} \varepsilon}{\mu_{\max} X_{\min}}, \quad X_{\min} = \min_k \| \text{row}_k(X) \|_1. \quad (18)$$

Let $Z$ be the output of Algorithm 1, with the stopping rule that the residual drops to the level $\varepsilon$ or below. Then $\text{supp}(Z) = \text{supp}(X)$.

Let $\hat{X}$ solve the least-squares problem

$$\hat{X} = \arg \min_B \| Y - \Phi B \|_{2,2}, \quad \text{s.t.} \quad \text{supp}(B) \subseteq \text{supp}(X), \quad \mathcal{L}B = 0. \quad (19)$$

Then

$$\| \hat{X} - X \|_{2,2} \leq \frac{2\varepsilon}{\sqrt{1 - \mu_{\max}(s - 1)}}. \quad (20)$$

The proof of Theorem 2 is given in Appendix B.

The main advantage of Theorem 2 over Theorem 1 is the guarantee of exact recovery of the support of $X$. Moreover, a better 2-norm error bound follows because now the gradient error is guaranteed to vanish outside a set of cardinality $O(\ell^{1-d})$: Let $\mathcal{L} \subset \mathbb{Z}^d$ be a finite lattice of $O(\ell^{-d})$ cardinality and $\{\mathcal{L}_l : l = 1, \ldots, L\}$ a partition of $\mathcal{L}$, i.e., $\mathcal{L} = \bigcup_l \mathcal{L}_l$ and $\mathcal{L}_l \cap \mathcal{L}_k = \emptyset$ for $l \neq k$. Let the scaled sets $\ell \mathcal{L}_l$, $l = 1, \ldots, L$, be the level sets of the object $V$ such that

$$V = \sum_{l=1}^L v_l \mathcal{I}_{\ell \mathcal{L}_l},$$

where $\mathcal{I}_{\ell \mathcal{L}_l}$ is the indicator function of $\ell \mathcal{L}_l$. The reconstructed object $\hat{V}$ from $\hat{X}$ given in (19) also takes the same form:

$$\hat{V} = \sum_{l=1}^L \hat{v}_l \mathcal{I}_{\ell \mathcal{L}_l}.$$
To fix the undetermined constant, we may assume that \( v_1 = \hat{v}_1 \). Since

\[
\| \Delta(V - \hat{V}) \|_{2,2} = O(\varepsilon)
\]

by (20) and the gradient error occurs only on the boundaries of \( \ell \mathbb{L}_l \) of cardinality \( O(\ell^{1-d}) \), we have

\[
|v_l - \hat{v}_l| = O(\varepsilon \ell^{(d-1)/2}) \quad \text{for all } l.
\]

Namely

\[
\| V - \hat{V} \|_{\infty} = O(\varepsilon \ell^{(d-1)/2})
\]

and thus

\[
\| V - \hat{V} \|_2 = O(\varepsilon / \sqrt{\ell}).
\]

4. Application: inverse scattering

In this section, we discuss the main application of the CJS formulation, that is, the TV-min for the inverse scattering problem.

A monochromatic wave \( u \) propagating in a heterogeneous medium characterized by a variable refractive index \( n^2(r) = 1 + v(r) \) is governed by the Helmholtz equation

\[
\nabla^2 u(r) + \omega^2(1 + v(r))u(r) = 0,
\]

(21)

where \( v \) describes the medium inhomogeneities. For simplicity, the wave velocity is assumed to be unity and hence the wavenumber \( \omega \) equals the frequency.

Consider the scattering of the incident plane wave

\[
u^i(r) = e^{i\omega r \cdot \hat{d}},
\]

(22)

where \( \hat{d} \) is the incident direction. The scattered field \( u^s = u - u^i \) then satisfies

\[
\nabla^2 u^s + \omega^2 u^s = -\omega^2 v u
\]

(23)

which can be written as the Lippmann–Schwinger equation:

\[
u^s(r) = \omega^2 \int_{\mathbb{R}^d} v(r')(u^i(r') + u^s(r'))G(r, r') dr',
\]

(24)

where \( G \) is the Green function for the operator \(- (\nabla^2 + \omega^2)\).

The scattered field necessarily satisfies Sommerfeld’s radiation condition

\[
\lim_{r \to \infty} r^{(d-1)/2} \left( \frac{\partial}{\partial r} - i \omega \right) u^s = 0,
\]

reflecting the fact that the energy which is radiated from the sources represented by the right-hand side of (23) must scatter to infinity.
Thus the scattered field has the far-field asymptotic
\[ u^s(r) = \frac{e^{i \omega |r|}}{|r|^{(d-1)/2}} \left( A(\hat{r}, \hat{d}, \omega) + O(|r|^{-1}) \right), \quad \hat{r} = r/|r|, \]
where \( A \) is the scattering amplitude and \( d \) the spatial dimension. In inverse scattering theory, the scattering amplitude is the measurement data determined by the formula [Colton and Kress 1998]
\[ A(\hat{r}, \hat{d}, \omega) = \frac{\omega^2}{4\pi} \int d r' v(r') u(r') e^{-i \omega r' \cdot \hat{r}}, \]
which under the Born approximation becomes
\[ A(\hat{r}, \hat{d}, \omega) = \frac{\omega^2}{4\pi} \int d r' v(r') e^{i \omega r' \cdot (\hat{d} - \hat{r})}. \]
(26)

For simplicity of notation we consider the two-dimensional case in detail. Let \( \mathbb{L} \subset \mathbb{Z}^2 \) be a square sublattice of \( m \) integral points. Suppose that \( s \) point scatterers are located in a square lattice of spacing \( \ell \):
\[ \ell \mathbb{L} = \{ r_j = \ell (p_1, p_2) : j = (p_1 - 1) \sqrt{m} + p_2, \ p = (p_1, p_2) \in \mathbb{L} \}. \]
(27)
In the context of inverse scattering, it is natural to treat the size of the discrete ambient domain \( \ell \mathbb{L} \) as being fixed independent of the resolution length \( \ell \). In particular, \( m \sim \ell^{-2} \) in two dimensions.

First let us motivate the inverse scattering sampling scheme in the case of point scatterers and let \( v_j, j = 1, \ldots, m \) be the strength of the scatterers. In other words, the total object is a sum of \( \delta \)-functions:
\[ v(r) = \sum_j v_j \delta(r - r_j). \]
(28)
Let \( \mathcal{S} = \{ r_i : j = 1, \ldots, s \} \) be the locations of the scatterers. Hence \( v_j = 0 \) for all \( r_j \notin \mathcal{S} \).

For point objects the scattering amplitude becomes a finite sum:
\[ A(\hat{r}, \hat{d}, \omega) = \frac{\omega^2}{4\pi} \sum_{j=1}^{m} v_j e^{i \omega r_j \cdot (\hat{d} - \hat{r})}. \]
(29)
In the Born approximation the exciting field \( u(r_j) \) is replaced by the incident field \( u^i(r_j) \).

5. Sampling schemes
Next we review the sampling schemes introduced in [Fannjiang 2010] for point objects (28).
Let \( \hat{d}_l \) and \( \hat{r}_l \), \( l = 1, \ldots, n \), be various incident and sampling directions for the frequencies \( \omega_l \), \( l = 1, \ldots, n \), to be determined later. Define the measurement vector \( Y = (y_l) \in \mathbb{C}^n \) with
\[
y_l = \frac{4\pi}{\omega^2 \sqrt{n}} A(\hat{r}_l, \hat{d}_l, \omega_l), \quad l = 1, \ldots, n.
\]
(30)
The measurement vector is related to the point object vector \( X = (v_j) \in \mathbb{C}^m \) by the sensing matrix \( \Phi \) as
\[
Y = \Phi X + E,
\]
(31)
where \( E \) is the measurement error. Let \( \theta_l \) and \( \tilde{\theta}_l \) be the polar angles of \( \hat{d}_l \) and \( \hat{r}_l \), respectively. The \((l, j)\)th-entry of \( \Phi \in \mathbb{C}^{n \times m} \) is
\[
n^{-1/2} e^{-i\omega_l \hat{r}_l \cdot r_j} e^{i\omega_l \hat{d}_l \cdot r_j} = n^{-1/2} e^{i\omega_l \ell(p_2 (\sin \theta_l - \sin \tilde{\theta}_l) + p_1 (\cos \theta_l - \cos \tilde{\theta}_l))},
\]
(32)
with \( j = (p_1 - 1) + p_2 \). Note that \( \Phi \) has unit 2-norm columns.

Let \((\xi_l, \zeta_l)\) be i.i.d. uniform random variables on \([-1, 1]^2\) and let \( \rho_l \) and \( \phi_l \) be the polar coordinates as in
\[
(\xi_l, \zeta_l) = \rho_l (\cos \phi_l, \sin \phi_l), \quad \rho_l = \sqrt{\xi_l^2 + \zeta_l^2} \leq \sqrt{2}.
\]
(33)
Let the sampling angle \( \tilde{\theta}_l \) be related to the incident angle \( \theta_l \) via
\[
\theta_l + \tilde{\theta}_l = 2\phi_l + \pi,
\]
(34)
and set the frequency \( \omega_l \) to be
\[
\omega_l = \frac{\Omega \rho_l}{\sqrt{2 \sin (\theta_l - \tilde{\theta}_l/2)}},
\]
(35)
where \( \Omega \) is a control parameter. Then the entries (32) of the sensing matrix \( \Phi \) under the condition
\[
\Omega \ell = \pi / \sqrt{2}
\]
(36)
are those of the random partial Fourier matrix
\[
e^{i\pi (p_1 \xi_l + p_2 \zeta_l)}, \quad l = 1, \ldots, n, \quad p_1, p_2 = 1, \ldots, \sqrt{m}.
\]
(37)

We consider two particular sampling schemes: The first employs multiple frequencies with the sampling angle always in the back-scattering direction, resembling the imaging geometry of synthetic aperture radar; the second employs only a single high frequency with the sampling angle in the forward direction, resembling the imaging geometry of X-ray tomography.
I. **Backward Sampling.** This scheme employs $\Omega$-band limited probes, that is, $\omega_l \in [-\Omega, \Omega]$. This and (35) lead to the constraint

$$\left| \sin \frac{\theta_l - \tilde{\theta}_l}{2} \right| \geq \frac{\rho_l}{\sqrt{2}}. \quad (38)$$

A simple way to satisfy (34) and (38) is to set

$$\phi_l = \tilde{\theta}_l = \theta_l - \pi, \quad (39)$$

$$\omega_l = \frac{\Omega \rho_l}{\sqrt{2}}, \quad (40)$$

where $l = 1, \ldots, n$. In this case the scattering amplitude is sampled exactly in the backward direction, resembling synthetic-aperture radar imaging. In contrast, exact forward sampling with $\tilde{\theta}_l = \theta_l$ almost surely violates the constraint (38).

II. **Forward Sampling.** This scheme employs single-frequency probes no less than $\Omega$:

$$\omega_l = \gamma \Omega, \quad \gamma \geq 1, \quad l = 1, \ldots, n. \quad (41)$$

We set

$$\theta_l = \phi_l + \arcsin \frac{\rho_l}{\gamma \sqrt{2}}, \quad (42)$$

$$\tilde{\theta}_l = \phi_l - \arcsin \frac{\rho_l}{\gamma \sqrt{2}}. \quad (43)$$

The difference between the incident angle and the sampling angle is

$$\theta_l - \tilde{\theta}_l = 2 \arcsin \frac{\rho_l}{\gamma \sqrt{2}}, \quad (44)$$

which diminishes as $\gamma \to \infty$. In other words, in the high-frequency limit, the sampling angle approaches the incident angle, resembling X-ray tomography [Natterer 1986].

6. **Piecewise constant objects**

Next let us consider the following class of piecewise constant objects:

$$v(r) = \sum_{p \in \mathbb{L}} v_p I_{\Box} \left( r - \frac{r}{\ell} - p \right), \quad \Box = \left[ -\frac{1}{2}, \frac{1}{2} \right]^2, \quad (45)$$

where $I_{\Box}$ is the indicator function of the unit square $\Box$. As remarked in Section 1, we think of the pixelated $v$ as a discrete approximation of some compactly supported function on $\mathbb{R}^2$ and having a well-defined limit as $\ell \to 0$. Set $V = (v_j) \in \mathbb{C}^m$ and $j = (p_1 - 1) \sqrt{m} + p_2$. 
The discrete version of (26) is, however, not exactly the same as (29) since extended objects have different scattering properties from those of point objects.

The integral on the right-hand side of (26), modulo the discretization error, is

\[ \int dr'v(r')e^{i\omega r'\cdot(\hat{d}-\hat{r})} = \sum_{p \in \mathbb{L}} v_pe^{i\omega\ell p\cdot(\hat{d}-\hat{r})} 1_{\square}(\ell) dr'. \]

Now letting \( \phi_l, \hat{r}_l, \omega_l, l = 1, \ldots, n \), be selected according to Scheme I or II and substituting them into the above equation, we obtain

\[ \int dr'v(r')e^{i\omega r'\cdot(\hat{d}_l-\hat{r}_l)} = \ell^2 \sum_{p \in \mathbb{L}} v_pe^{i\pi(p_1\xi_l+p_2\eta_l)} \int e^{i\pi(x_l+y_l)} dx dy \]

\[ = \ell^2 \sum_{p \in \mathbb{L}} v_pe^{i\pi(p_1\xi_l+p_2\eta_l)} \frac{2 \sin (\pi \xi_l/2)}{\pi \xi_l} \frac{2 \sin (\pi \eta_l/2)}{\pi \eta_l}. \]

Let

\[ x_j = \ell^2 v_p, \quad j = (p_1 - 1)\sqrt{m} + p_2, \]

and

\[ y_l = \frac{4\pi}{\omega_l^2 \tilde{g}_l \sqrt{n}} A(\hat{r}_l, \hat{d}_l, \omega_l) + E_l, \quad l = 1, \ldots, n, \]

where

\[ \tilde{g}_l = \frac{2 \sin (\pi \xi_l/2)}{\pi \xi_l} \frac{2 \sin (\pi \eta_l/2)}{\pi \eta_l} \]

and \( E = (e_l) \) is the noise vector.

Define the sensing matrix \( \Phi = [\phi_{kp}] \) as

\[ \phi_{kp} = \frac{1}{\sqrt{n}} e^{i\pi(p_1\xi_k+p_2\eta_k)}, \quad p = (p_1 - 1)\sqrt{m} + p_2, \quad p_1, p_2 = 1, \ldots, \sqrt{m}. \]

Then the system above can be written in the same form as (31):

\[ Y = \Phi X + E, \quad X = (x_j), \]

where the data and error vectors have been modified as above to account for the differences between extended and point objects.

Our goal is to establish the performance guarantee for TV-min

\[ \min \| Z \|_{TV}, \quad \text{s.t.} \quad \| Y - \Phi Z \|_2 \leq \| E \|_2. \]

We accomplish this by transforming (48) into BPDN for CJS (13).

Define \( X = (X_1, X_2) \) with

\[ (X_1, X_2) = \ell^2(\Delta_1 V, \Delta_2 V) \in \mathbb{C}^{m \times 2}. \]
Suppose the support of \( \{v_{p+e_1}, v_{p+e_2}\} \) is contained in \( \mathcal{L} \). Simple calculation yields
\[
y_l = \frac{\ell^2}{\sqrt{n}} e^{i\pi \xi_l} \sum_{p \in \mathcal{L}} v_{p+e_1} e^{i\pi(p_1 \xi_l + p_2 \eta_l)} = \frac{\ell^2}{\sqrt{n}} e^{i\pi \eta_l} \sum_{p \in \mathcal{L}} v_{p+e_2} e^{i\pi(p_1 \xi_l + p_2 \eta_l)}
\]
and thus
\[
(e^{-i\pi \xi_l} - 1) y_l = \frac{\ell^2}{\sqrt{n}} \sum_{p \in \mathcal{L}} (v_{p+e_1} - v_p) e^{i\pi(p_1 \xi_l + p_2 \eta_l)}, \quad (49)
\]
\[
(e^{-i\pi \eta_l} - 1) y_l = \frac{\ell^2}{\sqrt{n}} \sum_{p \in \mathcal{L}} (v_{p+e_2} - v_p) e^{i\pi(p_1 \xi_l + p_2 \eta_l)}. \quad (50)
\]
Define \( Y = (Y_1, Y_2) \) with
\[
Y_1 = ((e^{-i\pi \xi_l} - 1)y_l), \quad Y_2 = ((e^{-i\pi \eta_l} - 1)y_l) \in \mathbb{C}^n,
\]
and \( E = (E_1, E_2) \) with
\[
E_1 = ((e^{-i\pi \xi_l} - 1)e_l), \quad E_2 = ((e^{-i\pi \eta_l} - 1)e_l) \in \mathbb{C}^n. \quad (51)
\]
We rewrite (47) in the form
\[
Y = \Phi X + E, \quad (52)
\]
subject to the constraint
\[
\Delta_1 X_2 = \Delta_2 X_1 \quad (53)
\]
which is the discrete version of curl-free condition. This ensures that the reconstruction by line integration of \( (v_p) \) from \( X \) is consistent (that is, path-independent).

To see that (53) is necessary and sufficient for the recovery of \( (v_p) \), consider, for example, the notations in Figure 1 and suppose \( v_{0,0} \) is known. By definition of the difference operators \( \Delta_1 \) and \( \Delta_2 \) we have
\[
v_{1,0} = v_{0,0} + (\Delta_1 V)_{0,0}, \quad v_{0,1} = v_{0,0} + (\Delta_2 V)_{0,0}.
\]
In general, we can determine \( v_p, p \in \mathcal{L} \), iteratively from the relationship
\[
v_{p+e_1} = v_p + (\Delta_1 V)_p, \quad v_{p+e_2} = v_p + (\Delta_2 V)_p,
\]
and the knowledge of \( V \) at any grid point. The path-independence in evaluating \( v_{p_1+1,p_2+1} \),
\[
v_{p_1+1,p_2+1} = v_{p_1,p_2} + (\Delta_1 V)_{p_1,p_2} + (\Delta_2 V)_{p_1+1,p_2}
\]
implies that
\[
(\Delta_2 V)_{p_1+1,p_2} - (\Delta_2 V)_{p_1,p_2} = (\Delta_1 V)_{p_1,p_2+1} - (\Delta_1 V)_{p_1,p_2},
\]
which is equivalent to (53).

Now (47) is equivalent to (52) with the constraint (53) provided that the value of $V$ at (any) one grid point is known. The equivalence between the original TV-min (48) and the CJS formulation (13) with $\Phi_j = \Phi$ for all $j$, then hinges on the equivalence of their respective feasible sets which can be established under the assumption of Gaussian noise. When $E$ in (47) is Gaussian noise, then so is $E_c$, and vice versa, with variances precisely related to each other.

The random partial Fourier measurement matrix satisfies the RIP with $n = o(s)$, up to a logarithmic factor [Candès et al. 2006], while its mutual coherence $\mu$ behaves like $o(n^{-1/2})$ [Fannjiang et al. 2010]. Therefore (18) implies the sparsity constraint $s = o(\sqrt{n})$ for the greedy approach which is more stringent than $s = o(n)$ for the BPDN approach.

7. Conclusion

We have developed a general compressive sensing (CS) theory (Theorems 1 and 2) for constrained joint sparsity with multiple sensing matrices and obtained performance guarantees parallel to those for CS theory for a single measurement vector and matrix.

From the general theory we have derived 2-norm error bounds for the object and the gradient, independent of the ambient dimension, for total variation minimization (TV-min) and greedy estimates of piecewise constant objects.

In addition, the constrained joint sparsity (CJS) greedy algorithm can recover exactly the gradient support (that is, the edges of the object) leading to an improved 2-norm error bound. Although the CJS greedy algorithm needs a higher number of measurement data points than TV-min for Fourier measurements the incoherence property required is much easier to check, and is often the only practical way to
verify the restricted isometry property when the measurement matrix is not independently and identically distributed or Fourier.

We end by presenting a numerical example demonstrating the noise stability of TV-min. Efficient algorithms for TV-min denoising/deblurring exist [Beck and Teboulle 2009; Weiss et al. 2009]. We use the open source code $\ell_1$-MAGIC for our simulation.

Figure 2 shows the $256 \times 256$ image of the Shepp–Logan phantom and the modulus of its gradient. Clearly the sparsity ($s = 2,184$) of the gradient is much smaller than that of the original image. We take 10,000 Fourier measurement data points for the $\ell_1$-min (1) and TV-min (5) reconstructions.

Because the image is not sparse, $\ell_1$-min reconstruction produces a poor result even in the absence of noise, shown in Figure 3. The relative error is 66.8% in

Figure 3. Noiseless $\ell_1$-min reconstructed image (left) and the differences (middle) from the original image. The plot on the right is the gradient of the reconstructed image.
Figure 4. TV-reconstructed image with 5% (top left) and 10% (bottom left) and the respective differences (middle) from the original image. The plots on the right column are the magnitudes of the reconstructed image gradients.

the $\ell_2$ norm and 72.8% in the TV norm. Only the outer boundary, which has the largest pixel values, is reasonably recovered.

Figure 4 shows the results of TV-min reconstruction in the presence of 5% (top) or 10% (bottom) noise. Evidently, the performance is greatly improved.

Appendix A: Proof of Theorem 1

The argument is patterned after [Candès 2008] with adaptation to the CJS setting.

**Proposition 1.** We have

$$|\Re\langle \varphi(Z), \varphi(Z') \rangle| \leq \delta_{s+s'}\|Z\|_{2,2}\|Z'\|_{2,2}$$

for all $Z, Z'$ supported on disjoint subsets $T, T' \subset \{1, \ldots, m\}$ with $|S| \leq s$ and $|S'| \leq s'$.

**Proof.** Without loss of generality, suppose that $\|Z\|_{2,2} = \|Z'\|_{2,2} = 1$. Since $Z \perp Z'$, $\|Z \pm Z'\|_{2,2}^2 = 2$. Hence we have from the RIP (14)

$$2(1 - \delta_{s+s'}) \leq \|\varphi(Z \pm Z')\|_{2,2}^2 \leq 2(1 + \delta_{s+s'}).$$

(54)
By the parallelogram identity and (54)
\[ |\Re \langle \varphi(Z), \varphi(Z') \rangle| = \frac{1}{4} \| \varphi(Z) + \varphi(Z') \|_2^2 - \| \varphi(Z) - \varphi(Z') \|_2^2 \leq \delta_{s+s'}, \]
which proves the proposition. \(\square\)

By the triangle inequality and the fact that \(X\) is in the feasible set we have
\[ \| \varphi(\hat{X} - X) \|_2 \leq \| \varphi(\hat{X}) - Y \|_2 + \| Y - \varphi(X) \|_2 \leq 2\epsilon. \quad (55) \]
Set \(\hat{X} = X + D\) and decompose \(D\) into a sum of \(D_{S_0}, D_{S_1}, D_{S_2}, \ldots\), each of row sparsity at most \(s\). Here \(S_0\) corresponds to the locations of the \(s\) largest rows of \(X\); \(S_1\) the locations of the \(s\) largest rows of \(D_{S_0}^c\); \(S_2\) the locations of the next \(s\) largest rows of \(D_{S_0}^c\); and so on.

Step (i). Define the norm
\[ \| Z \|_{\infty,2} = \max_j \| \text{row}_j(Z) \|_2. \]
For \(j \geq 2\),
\[ \| D_{S_j} \|_2 \leq s^{1/2} \| D_{S_j} \|_{\infty,2} \leq s^{-1/2} \| D_{S_{j-1}} \|_2, \]
and hence
\[ \sum_{j \geq 2} \| D_{S_j} \|_2 \leq s^{-1/2} \sum_{j \geq 1} \| D_{S_j} \|_1,2 \leq s^{-1/2} \| D_{S_0}^c \|_1,2. \quad (56) \]
This yields, by the Cauchy–Schwarz inequality,
\[ \| D_{(S_0\cup S_1)^c} \|_2 \leq \| \sum_{j \geq 2} D_{S_j} \|_2 \leq \sum_{j \geq 2} \| D_{S_j} \|_2 \leq s^{-1/2} \| D_{S_0}^c \|_1,2. \quad (57) \]
Also we have
\[ \| X \|_1,2 \geq \| \hat{X} \|_1,2 = \| X_{S_0} + D_{S_0} \|_1,2 + \| X_{S_0}^c + D_{S_0}^c \|_1,2 \geq \| X_{S_0} \|_1,2 - \| D_{S_0} \|_1,2 - \| X_{S_0}^c \|_1,2 + \| D_{S_0}^c \|_1,2, \]
which implies
\[ \| D_{S_0}^c \|_1,2 \leq 2\| X_{S_0} \|_1,2 + \| D_{S_0} \|_1,2. \quad (58) \]
Note that \(\| X_{S_0} \|_1,2 = \| X - X^{(s)} \|_1,2\) by definition. Applying (57), (58), and the Cauchy–Schwarz inequality to \(\| D_{S_0} \|_1,2\) gives
\[ \| D_{(S_0\cup S_1)^c} \|_2 \leq \| D_{S_0} \|_2 + 2\epsilon_0, \quad (59) \]
where \(\epsilon_0 \equiv s^{-1/2} \| X - X^{(s)} \|_1,2\).
Step (ii). Define the inner product
\[ \langle A, B \rangle = \sum_{i,j} A_{ij}^* B_{ij}. \]
Observe that
\[ \| \varphi(D_{S_0 \cup S_1}) \|_{2,2}^2 = \langle \varphi(D_{S_0 \cup S_1}), \varphi(D) \rangle - \left( \varphi(D_{S_0 \cup S_1}), \sum_{j \geq 2} \varphi(D_{S_j}) \right) \]
\[ = \Re \langle \varphi(D_{S_0 \cup S_1}), \varphi(D) \rangle - \sum_{j \geq 2} \Re \langle \varphi(D_{S_0 \cup S_1}), \varphi(D_{S_j}) \rangle \]
\[ = \Re \langle \varphi(D_{S_0 \cup S_1}), \varphi(D) \rangle - \sum_{j \geq 2} [\Re \langle \varphi(D_{S_0}), \varphi(D_{S_j}) \rangle + \Re \langle \varphi(D_{S_1}), \varphi(D_{S_j}) \rangle]. \quad (60) \]

From (55) and the RIP (14) it follows that
\[ |\langle \varphi(D_{S_0 \cup S_1}), \varphi(D) \rangle| \leq \| \varphi(D_{S_0 \cup S_1}) \|_{2,2} \| \varphi(D) \|_{2,2} \leq 2\varepsilon \sqrt{1 + \delta_2} \| D_{S_0 \cup S_1} \|_{2,2}. \]

Moreover, it follows from Proposition 1 that
\[ |\Re \langle \varphi(D_{S_0}), \varphi(D_{S_j}) \rangle| \leq \delta_2 \| D_{S_0} \|_{2,2} \| D_{S_j} \|_{2,2}, \quad (61) \]
\[ |\Re \langle \varphi(D_{S_1}), \varphi(D_{S_j}) \rangle| \leq \delta_2 \| D_{S_0} \|_{2,2} \| D_{S_j} \|_{2,2}, \quad (62) \]
for \( j \geq 2 \). Since \( S_0 \) and \( S_1 \) are disjoint:
\[ \| D_{S_0} \|_{2,2} + \| D_{S_1} \|_{2,2} \leq \sqrt{2} \sqrt{\| D_{S_0} \|_{2,2}^2 + \| D_{S_1} \|_{2,2}^2} = \sqrt{2} \| D_{S_0 \cup S_1} \|_{2,2}. \]

Also by (60)–(62) and the RIP,
\[ (1 - \delta_2) \| D_{S_0 \cup S_1} \|_{2,2}^2 \leq \| \varphi(D_{S_0 \cup S_1}) \|_{2,2}^2 \]
\[ \leq \| D_{S_0 \cup S_1} \|_{2,2} \left( 2\varepsilon \sqrt{1 + \delta_2} + \delta_2 \sum_{j \geq 2} \| D_{S_j} \|_{2,2} \right). \]

Therefore from (56) we obtain
\[ \| D_{S_0 \cup S_1} \|_{2,2} \leq \alpha \varepsilon + \rho s^{-1/2} \| D_{S_0} \|_{1,2}, \quad \alpha = \frac{2 \sqrt{1 + \delta_2}}{1 - \delta_2}, \quad \rho = \frac{\sqrt{2} \delta_2}{1 - \delta_2}, \]
and moreover by (58) and the definition of \( e_0 \)
\[ \| D_{S_0 \cup S_1} \|_{2,2} \leq \alpha \varepsilon + \rho \| D_{S_0} \|_{2,2} + 2 \rho e_0 \]
after applying the Cauchy–Schwartz inequality to bound \( \| D_{S_0} \|_{1,2} \) by \( s^{1/2} \| D_{S_0} \|_{2,2} \). Thus
\[ \| D_{S_0 \cup S_1} \|_{2,2} \leq (1 - \rho)^{-1}(\alpha \varepsilon + 2 \rho e_0) \]
if (14) holds.
Finally,
\[
\|D\|_{2,2} \leq \|D_{S_0 \cup S_1}\|_{2,2} + \|D_{(S_0 \cup S_1)'}\|_{2,2} \leq 2 \|D_{S_0 \cup S_1}\|_{2,2} + 2e_0
\]
\[
\leq 2(1 - \rho)^{-1}(\alpha \varepsilon + (1 + \rho)e_0),
\]
which is the desired result.

Appendix B: Proof of Theorem 2

We prove the theorem by induction.

Let \(\text{supp}(X) = \mathcal{S} = \{J_1, \ldots, J_s\}\) and

\[
X_{\text{max}} = \|\text{row}_{J_1}(X)\|_1 \geq \|\text{row}_{J_2}(X)\|_1 \geq \cdots \geq \|\text{row}_{J_s}(X)\|_1 = X_{\text{min}}.
\]

In the first step,
\[
\sum_{j=1}^{d} |\Phi_{j,1} Y_j| = \sum_{j=1}^{d} |X_{J_1} + X_{J_2} \Phi_{j,1} \Phi_j, J_1 + \cdots + X_{J_s} \Phi_{j,s} \Phi_j, J_s + \Phi_{j,1} E_j| \geq X_{\text{max}} - X_{\text{max}}(s - 1)\mu_{\text{max}} - \sum_j \|E_j\|_2. \tag{B.1}
\]

On the other hand, for any \(l \notin \text{supp}(X)\),
\[
\sum_{j=1}^{d} |\Phi_{j,l} Y_j| = \sum_{j=1}^{d} |X_{J_1} \Phi_{j,l} \Phi_j, J_1 + X_{J_2} \Phi_{j,l} \Phi_j, J_2 + \cdots + X_{J_s} \Phi_{j,l} \Phi_j, J_s + \Phi_{j,l} E_j| \leq X_{\text{max}} s\mu_{\text{max}} + \sum_j \|E_j\|_2. \tag{B.2}
\]

Hence, if
\[
(2s - 1)\mu_{\text{max}} + \frac{2 \sum_j \|E_j\|_2}{X_{\text{max}}} < 1,
\]
then the right-hand side of (B.1) is greater than the right-hand side of (B.2) which implies that the first index selected by OMP must belong to \(\text{supp}(X)\).

To continue the induction process, we state the straightforward generalization of a standard uniqueness result for sparse recovery to the joint sparsity setting [Donoho et al. 2006, Lemma 5.3].

**Proposition 2.** Let \(Z = \varphi(X)\) and \(Y = Z + E\). Let \(\mathcal{S}^k\) be a set of \(k\) indices and let \(A \in \mathbb{C}^{n \times d}\) with \(\text{supp}(A) = \mathcal{S}^k\). Define
\[
Y' = Y - \varphi(A) \tag{B.3}
\]
and
\[
Z' = Z - \varphi(A).
\]
Clearly, $Y' = Z' + E$. If $\mathcal{S}^k \subseteq \text{supp}(X)$ and the sparsity $s$ of $X$ satisfies $2s < 1 + \mu_{\text{max}}^{-1}$, then $Z'$ has a unique sparsest representation $Z' = \varphi(X')$ with the sparsity of $X'$ at most $s$.

Proposition 2 says that the selection of a column, followed by the formation of the residual signal, leads to a situation like before, where the ideal noiseless signal has no more representing columns than before, and the noise level is the same.

Suppose that the set $\mathcal{S}^k \subseteq \text{supp}(X)$ of $k$ distinct indices has been selected and that $A$ in Proposition 2 solves the following least-squares problem:

$$A = \arg \min \| Y - \Phi B \|_{2,2}, \quad \text{s.t.} \quad \text{supp}(B) \subseteq \mathcal{S}^k,$$

without imposing the constraint $\mathcal{L}$. This is equivalent to the concatenation $A = [A_j]$ of $d$ separate least-squares solutions

$$A_j = \arg \min_{B_j} \| Y_j - \Phi_j B_j \|_2, \quad \text{s.t.} \quad \text{supp}(B_j) \subseteq \mathcal{S}^k.$$  \hfill (B.5)

Let $\Phi_{j,\mathcal{S}^k}$ be the column submatrix of $\Phi_j$ indexed by the set $\mathcal{S}^k$. By (B.3) and (B.5), we have $\Phi_{j,\mathcal{S}^k} Y_j = 0$ for all $j$, which implies that no element of $\mathcal{S}^k$ gets selected at the $(k+1)$-st step.

In order to ensure that some element in $\text{supp}(X) \setminus \mathcal{S}^k$ gets selected at the $(k+1)$-st step we only need to repeat the calculation (B.1)–(B.2) to obtain the condition

$$(2s - 1)\mu_{\text{max}} + \frac{2 \sum_j \| E_j \|_2}{\| X_{J_{k+1}} \|_1} < 1. \hfill (B.6)$$

Since $\sum_j \| E_j \|_2 \leq \sqrt{d} \| E \|_2,2 \leq \sqrt{d} \varepsilon$, (B.6) follows from

$$(2s - 1)\mu_{\text{max}} + \frac{2\sqrt{d} \varepsilon}{X_{\text{min}}} < 1, \hfill (B.7)$$

which is the same as (18) and allows us to apply Proposition 2 repeatedly.

By the $s$-th step, all elements of the support set are selected and by the nature of the least-squares solution the 2-norm of the residual is at most $\varepsilon$. Thus the stopping criterion is met and the iteration stops after $s$ steps.

On the other hand, it follows from the calculation

$$\sum_j \| Y_j \|_2 \geq \sum_{j=1}^d | \Phi_{J_{k+1}}^* Y_j^c | = \sum_j \| X_{J_{k+1}} \|_1 + \sum_{i=k+2}^s \| X_{J_i} \|_1 \| \Phi_{J_{k+1}}^* \|_1 - \sum_j \| E_j \|_2$$

$$\geq \| \text{row}_{J_{k+1}}(X) \|_1 - \mu_{\text{max}}(s - k - 1) \| \text{row}_{J_{k+1}}(X) \|_1 - \sum_j \| E_j \|_2$$

$$\geq (1 - \mu_{\text{max}}(s - k - 1)) \| \text{row}_{J_{k+1}}(X) \|_1 - \sum_j \| E_j \|_2,$$
and (B.7) (equivalently, \(X_{\text{min}}(1 - \mu_{\text{max}}(2s - 1)) > 2\sqrt{d\varepsilon}\)) that \(\|Y\|_{1,2} > \sqrt{d\varepsilon}\) for \(k = 0, 1, \ldots, s - 1\). Thus the iteration does not stop until \(k = s\).

Since \(\hat{X}\) is the solution of the least-squares problem (19), we have

\[
\|Y - \Phi\hat{X}\|_{2,2} \leq \|Y - \Phi X\|_{2,2} \leq \varepsilon
\]

and

\[
\|\Phi(X - \hat{X})\|_{2,2}^2 \leq 2\|Y - \Phi X\|_{2,2}^2 + 2\|Y - \Phi\hat{X}\|_{2,2}^2 \leq 2\varepsilon^2,
\]

which implies

\[
\|\hat{X} - X\|_{2,2} \leq \sqrt{2\varepsilon/\lambda_{\text{min}}},
\]

where

\[
\lambda_{\text{min}} = \min_{j}\{\text{the } s\text{-th singular value of the column submatrix of } \Phi_j \text{ indexed by } \mathcal{S}\}.
\]

The desired error bound (20) can now be obtained from the following result [Donoho et al. 2006, Lemma 2.2].

**Proposition 3.** Suppose \(s < 1 + \mu(\Phi_j)^{-1}\). Every \(m \times s\) column submatrix of \(\Phi_j\) has the \(s\)-th singular value bounded below by \(\sqrt{1 - \mu(\Phi_j)(s - 1)}\).

By Proposition 3, \(\lambda_{\text{min}} \geq \sqrt{1 - \mu_{\text{max}}(s - 1)}\) and thus

\[
\|\hat{X} - X\|_{2,2} \leq \frac{\sqrt{2\varepsilon}}{\sqrt{1 - \mu_{\text{max}}(s - 1)}}.
\]

**Acknowledgements**

I thank Stan Osher and Justin Romberg for the suggestion of publishing this note at the Institute for Pure and Applied Mathematics workshop “Challenges in Synthetic Aperture Radar,” February 6–10, 2012. I thank the anonymous referees and Deanna Needell for pointing out the reference [Needell and Ward 2012] which helps me appreciate more deeply the strengths and weaknesses of my approach. I am grateful to Wenjing Liao for preparing Figures 2–4.
